

Shrinking of fishes exacerbates impacts of global ocean changes on marine ecosystems

Method

Dynamic Bioclimate Envelope Model (DBEM)

As a first step, we predicted the current (1970-2000) distribution map of each species an algorithm described in [^{1,2}]. This algorithm estimates the relative abundance of a species on a 30' latitude x 30' longitude grid of the world ocean. Input parameters for DBEM include the species' maximum and minimum depth limits, northern and southern latitudinal range limits, an index of association to major habitat types (seamounts, estuaries, inshore, offshore, continental shelf, continental slope and the abyssal) and known occurrence boundaries. The parameter values of each species, which are posted on the *Sea Around Us* Project website (<http://www.searroundus.org/distribution/search.aspx>), were derived from data in online databases, mainly FishBase (www.fishbase.org). Jones *et al.*³ compared the predicted species distribution from this algorithm with empirically observed occurrence records and found that the algorithm has high predictive power, and that its skills are comparable with other commonly used species distribution modelling approach for marine species such as Maxent⁴ and Aquamap⁵.

As a second step, we used DBEM to identify the 'environmental preference profiles' of the studied species, defined by outputs from the Earth System Models, including sea water temperature (bottom and surface), depth, salinity, distance from sea-ice and habitat types. Preference profiles are defined as the suitability of each of these environmental conditions to each species, with suitability calculated by overlaying environmental data (1970-2000) with maps of relative abundance of the species⁶. For example, for each species, DBEM calculated a temperature preference profile for the adult and pre-recruit phases based on the relative abundance and the computed recruitment strength of the species. Sea surface temperature is then

used for temperature preference profiles for pre-recruit phase while bottom temperature is applied to preference profiles for adult demersal species.

The model represents individual growth of fish using a growth function:

$$W_t = W_\infty [1 - e^{-K(t-t_0)}]^{1/(1-a)} \quad \text{eq. S1}$$

$$W_\infty = \left(\frac{H}{k}\right)^{\frac{1}{1-a}} \quad \text{eq. S2}$$

$$K = k \cdot (1 - a) \quad \text{eq. S3}$$

where $a = 0.7$, $H = g \cdot [\text{O}_2] \cdot e^{j/T}$ and $k = h \cdot e^{-i/T}$ in which T is environmental temperature, j and $i = E_a/R$ with E_a and R representing the activation energy and Boltzmann constant in the Arrhenius equation⁷ (Figure S1). k is the coefficient for the catabolic term of the growth equation which is independent of oxygen supply⁸.

We set values of j based on empirically estimated metabolic scaling exponents. Meta-analysis of the resting metabolic rate of teleosts suggests that the within-species Q_{10} of temperature ranges from 0.45 to 3.41, with a median of 2.4⁹. We assume that the resting metabolic rate represents metabolic demand for basic body functions and maintenance. Thus, we calculated a i in the Arrhenius equation for catabolism that would result in the reported Q_{10} over a wide temperature range (with median of the temperature preference profiles of the studied species that ranges between 1 – 28°C) of approximately 8. Given that anabolism is considered to be less temperature sensitive than catabolism¹⁰ and based on the fact that the slope of the regression between $\log(K)$ and $\log(W_\infty)$ among different populations of a species is ≈ 0.7 ⁸, we estimate that j should be ≈ 4.5 . We tested the effect of alternative values of a , i , and j on the simulation for Atlantic cod to examine the sensitivity of the results to these parameters.

The mean values of the coefficients g and h were derived from asymptotic weight (W_∞), von Bertalanffy growth parameter K , the average environmental temperature (T) and oxygen concentration [O_2] estimated from the predicted current distribution and the average T and [O_2] within their distribution (weighted by the relative abundance of the species). Parameter values for asymptotic (L_∞) and K were obtained from FishBase (www.fishbase.org). W_∞ was then calculated from the length-weight conversion:

$$W_\infty = a \cdot L_\infty^b$$

where a and b are the length-weight conversion parameters obtained from FishBase. In a few cases where published values of a and b were not available, we assumed that W_∞ (in g) scales isometrically (i.e., $b = 3$) with L_∞ (in cm) and $a = 0.01$, which approximately corresponds to the fusiform shape of a cod (*Gadus morhua*; www.fishbase.org). In any case, the parameter a is a scaling factor and its value does not affect the projected change in body weight. The model then simulates the population dynamics and changes in relative abundance on each spatial cell given changes in annual average sea water temperature (surface and bottom), ocean current, salinity, oxygen concentration and sea-ice concentration projected by the Earth System Models.

Carrying capacity is expressed as a function of expected biomass per recruit and recruitment. Expected biomass per recruit was determined by a size-based population model ⁷. The size-transition matrix (X), a matrix of probabilities of an individual growing from a particular body-size class to other size classes in a time step (year), was computed from [¹¹]:

$$\theta_{y,l',l} = \exp \left[-\frac{(\bar{l}_l - [l_\infty(1-e^{-K}) + \bar{l}_{l'} e^{-K}])^2}{2\sigma^2} \right] \quad \text{and}$$

$$X_{l',l} = \frac{\theta_{l',l}}{\sum_{l'} \theta_{l',l}}$$

where l_∞ is the asymptotic length, l and l' are adjacent length classes, y is age of fish, σ is the variation in growth which is assumed to have a coefficient of variation of 20% and is independent of length and age. The biomass per recruit (BPR) was calculated from:

$$BPR = \sum_y \sum_l \bar{W}_l \cdot X_{l',l} \cdot e^{-M}$$

where \bar{W} is mean weight of the fish in length class l . Natural mortality rate (M) was predicted from Pauly's empirical equation ¹²:

$$\log M = 0.2107 - 0.0824 \cdot \log W_{inf} + 0.6757 \cdot \log K + 0.4627 \cdot \log T'$$

where T' is temperature in degree Celsius.

Initial relative recruitment strength (R) is calculated from the initial relative abundance (A , normalized across the 30' x 30' degree resolution grid) and calculated biomass per recruit in each cell, as $BPR = c \cdot A / R$. where c is a constant that scales from relative abundance to absolute abundance. Thus, $R = c \cdot A / BPR$ and $A = BPR \cdot R / c$.

The model simulates changes in relative abundance of a species by:

$$\frac{dA_i}{dt} = \sum_{j=1}^N G_i + L_{ji} + I_{ji}$$

where A_i is the relative abundance of a 30' x 30' cell i, G is the intrinsic population growth and L_{ji} and I_{ji} are settled larvae and net immigrated adults from surrounding cells (j), respectively.

Intrinsic population growth is modeled by a logistic equation:

$$G_i = r \cdot A_i \cdot \left(1 - \frac{A_i}{A_{\infty,i}}\right)$$

where r is the intrinsic rate of population increase, A_∞ is the carrying capacity calculated from the expected biomass per recruit and recruitment (see above). The model explicitly represents larval dispersal through ocean current with an advection-diffusion-reaction model (see [^{6,13}] for details).

Thus, changes in ocean conditions will be transformed by the model into changes in life history, growth, carrying capacity, population growth, net migration, and thus, relative abundance of a species, in each cell it occupies. Given the projected changes in ocean conditions under climate change scenarios, the model simulates the annual changes in distribution of relative abundance of each species on the global 30' x 30' grid.

Scenarios of biogeochemical changes in the ocean

Our scenario of ocean conditions is based on outputs from the Earth System Model (ESM2.1)¹⁴ developed at the Geophysical Fluid Dynamic Laboratory (GFDL) of the US National Oceanic and Atmospheric Administration (NOAA) and the Earth System Model IPSL-CM4-LOOP¹⁵ developed by the French Institut Pierre Simon Laplace (IPSL). ESM2.1 is a dynamic atmosphere-ocean general circulation model ¹⁶ coupled to a marine biogeochemistry model which includes major nutrients and three phytoplankton functional groups with variable stoichiometry ¹⁷. The IPSL-CM4-LOOP model is a fully coupled climate and carbon cycle model

(e.g. see [¹⁵] and references therein). It consists of the Laboratoire de Météorologie Dynamique atmospheric model (LMDZ-4) with a horizontal resolution of about $3.6^\circ \times 2.5^\circ$ and 19 vertical levels, coupled to the OPA-8 ocean model with a horizontal resolution of 2° to 0.5° and 31 vertical levels and the LIM sea ice model. The terrestrial biosphere is represented by the global vegetation model ORCHIDEE and the marine carbon cycle is simulated by the PISCES model.

The scenario considered here is the IPCC's Special Report on Emission Scenario (SRES) A2, which assumes atmospheric CO₂ concentration to become around 860 ppm by 2100. We interpolated the original resolution of the model outputs on a 30' x 30' grid by using the nearest neighbour method. The outputs from the Earth System Models considered by the DBEM included sea bottom temperature, sea surface temperature, sea bottom oxygen concentration, surface current advection (horizontal), salinity and sea ice concentration. Annual average values of each variable were used. Delineation of ocean basin is based on the United Nations Food and Agriculture Organization Statistical Area (Figure S4).

Calculation of mean assemblage-level body weight

We calculated the mean (geometric) assemblage-level body weight from the predicted distribution and maximum body weight of the modelled fish species. We identified species that were predicted to occur in each 30' lat. x 30' lat. cell. We then calculated the mean (geometric) predicted maximum body weight in each cell weighted by the predicted relative abundance of each species (corrected by area of the grid cells) and their historically observed maximum catch. Fish body weights range over several orders of magnitude, thus geometric mean provides a better representation of the relative changes in body weight across the size spectrum of the assemblage. Historically observed maximum catch was calculated from time-series catch data (1950 to the

present) obtained from the United Nations Food and Agriculture Organization (FAO) and processed by the *Sea Around Us* project (www.searroundus.org). For each species, we calculated the average maximum annual catch from the mean of the five highest annual catches across the time-series. The mean assemblage-level body weight (W') at cell i was then calculated from:

$$W'_i = \frac{\sum_{j=1}^n \log(W_{\infty i,j}) \cdot Abd_{i,j} \cdot C_j}{\sum_{j=1}^n Abd_{i,j} \cdot C_j}$$

where $W_{\infty i,j}$ is maximum body weight of species j , Abd is the predicted relative abundance and C is the maximum catch (scaled to the area of each cell). The values of W'_i are calculated for each year from 1971 to 2060.

Calculation of latitudinal centroid shift

Latitudinal centroid (LC) of each species was calculated from:

$$LC = \frac{\sum_{i=1}^n Lat_i \cdot Abd_i}{\sum_{i=1}^n Abd_i}$$

where Lat_i is the latitude of the centre of the spatial cell (i), Abd is the predicted relative abundance in the cell (corrected by area of the grid cells), and n is the total number of cells. Range shift was then calculated from difference between the latitudinal centroid of the projected and reference years. Shift in distance (km) was then calculated from:

$$Distance\ shift = \cos^{-1} \cdot \left[\sin\left(Lat_m \cdot \frac{\pi}{180}\right) \cdot \sin\left(Lat_n \cdot \frac{\pi}{180}\right) + \cos\left(Lat_m \cdot \frac{\pi}{180}\right) \cdot \cos\left(Lat_n \cdot \frac{\pi}{180}\right) \right] \cdot 6378.2$$

Supplementary figures

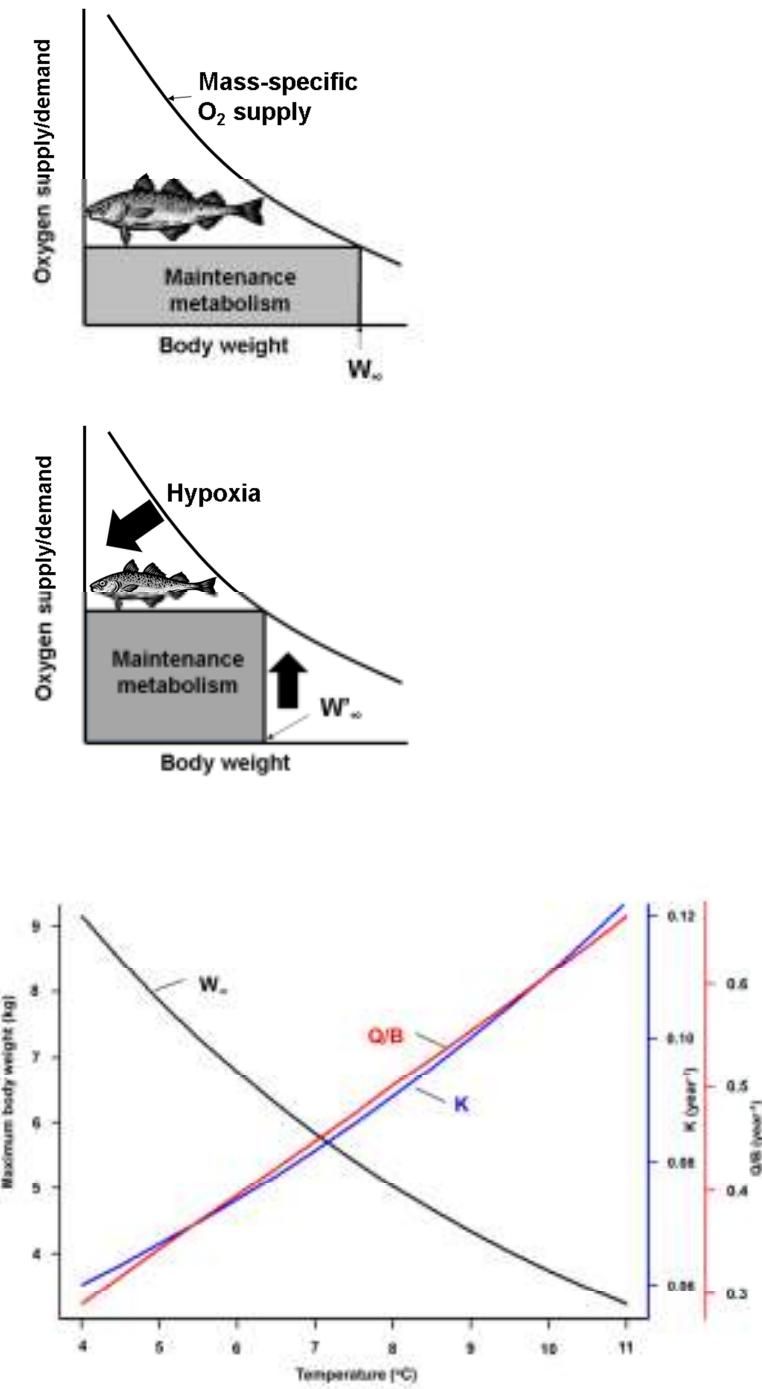

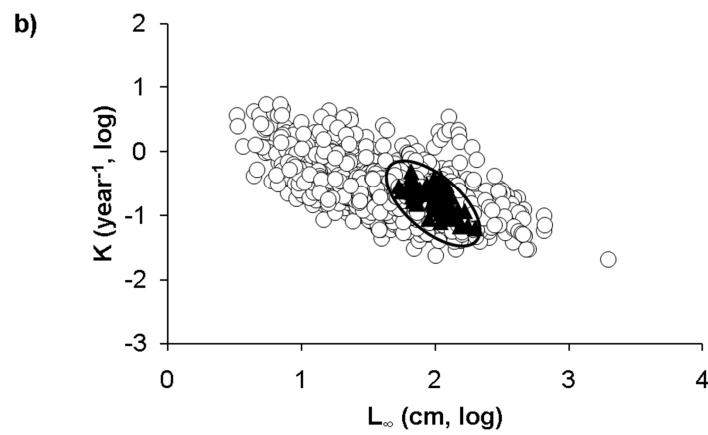

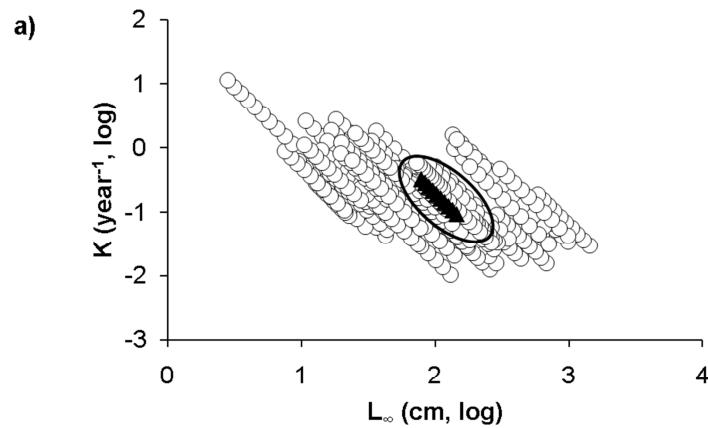

Figure S1. Schematic diagram illustrating how oxygen supply and demand determine maximum (i.e., asymptotic) body weight (W_∞) (upper panel), the effects of warming (black upward arrow) and hypoxia on growth and asymptotic weight (W'_∞) (middle panel) (Redrawn from [7]), and

example of the theoretical relationship between W_∞ , von Bertalanffy growth parameter K, consumption to biomass ratio (Q/B) of Atlantic cod and temperature of its habitat. The relationship of W_∞ and temperature is predicted from eq. S1, K and temperature is from eq. S2, and Q/B and temperature is from an empirical equation to estimate Q/B from temperature (T), asymptotic body size (W_∞) aspect ratio of the fish (A), and type of food item (F)¹⁸. i.e., $Q/B = -0.1775 - 0.2018 \ln W_\infty + 0.6121 \ln T + 0.5156 \ln A + 1.26F$.

c)

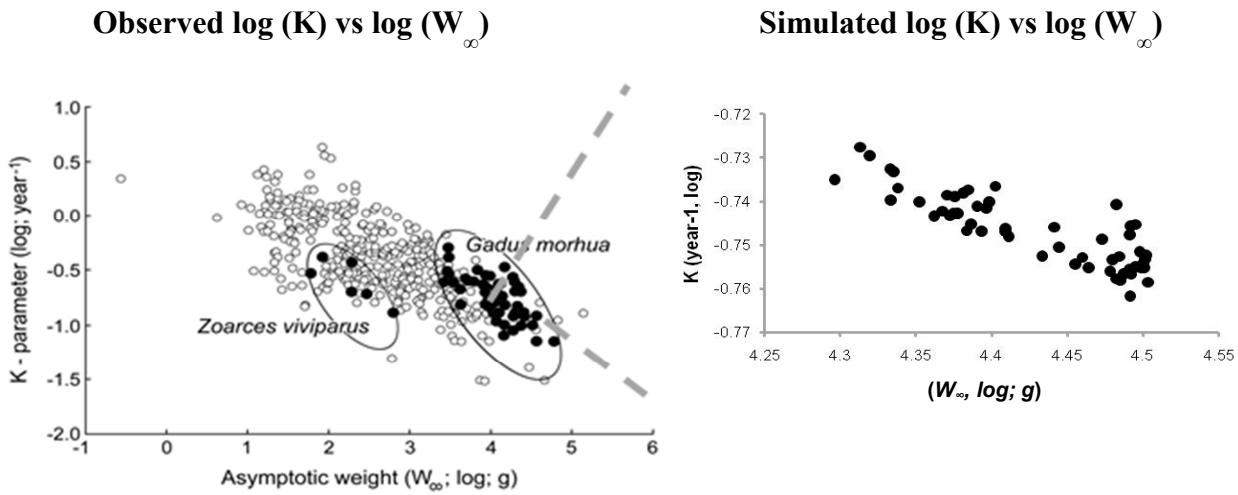

Figure S2. Plot of $\log K$ against $\log L_\infty$ of (a) 120 demersal fishes over the 5th and 95th percentile of their predicted habitat temperature (as predicted from the dynamic bioclimate envelope model); (b) published empirical estimates of VBGF of 2015 fishes (available from FishBase); and (c) Comparing observed changes in growth parameters (left) with simulated changes from the dynamic bioclimate envelope model under future scenarios of changes in ocean biogeochemistry and physical conditions (right) (redrawn from Cheung *et al.* 2011). The black triangles in (a) and (b) represent predictions and estimates for different Atlantic cod populations. Using Atlantic cod as an example, the predicted slope between $\log K$ and $\log L_\infty$ not significantly different ($p < 0.05$) from the slope calculated from observed $\log K$ and $\log L_\infty$ (Taylor 1958).

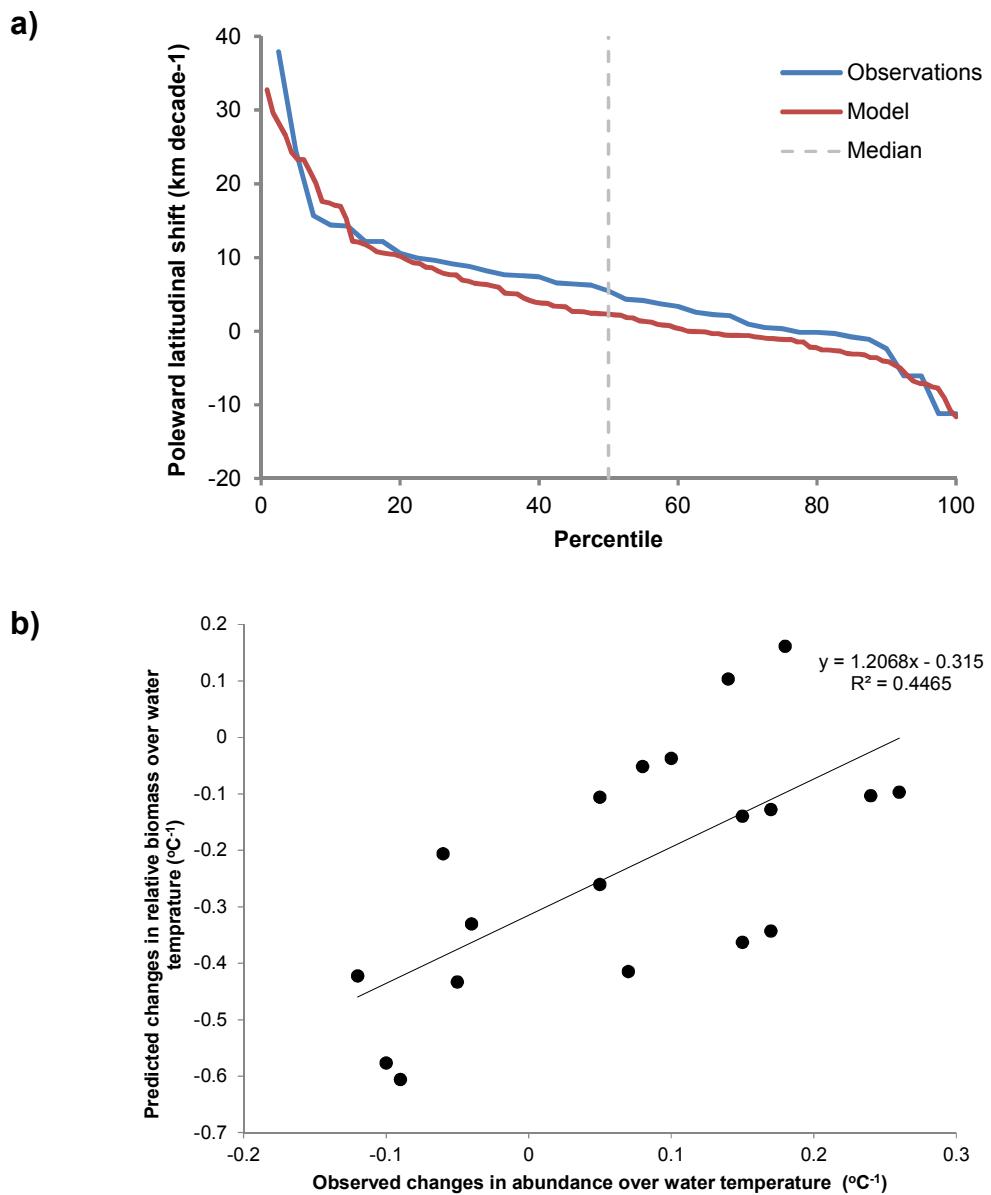

Figure S3. Comparison between observations and predictions from Dynamic Bioclimate Envelope Model for (A) Bering Sea (Large Marine Ecosystem) and (B) waters around the UK (North Sea and Irish Sea Large Marine Ecosystems). For (A), observations (blue line) are estimated rate of change of latitudinal centroid calculating using catch-per-unit-effort data from fishing survey in 1975 - 2001 in the Bering Sea ($N = 40$) (see ¹⁹) while predictions (red line) are calculated rate of change of latitudinal centroids ($N = 114$) in the Bering Sea Large

Marine Ecosystem from model outputs that are driven by historical simulation of global ocean biogeochemistry through the NOAA's GFDL ESM2.1 forced with historical reanalysis climate data. For (B), observations are the average estimated slope of abundance against water temperature from 1975 to 2007 (see ²⁰ for details) while predictions are the slope of change in modelled relative biomass in the North Sea and Irish Sea Large Marine Ecosystems of species that correspond to Simpson *et al.* (2011) (N = 19). Only species that show significant trends between abundance and temperature ($p < 0.05$) are included in the analysis.

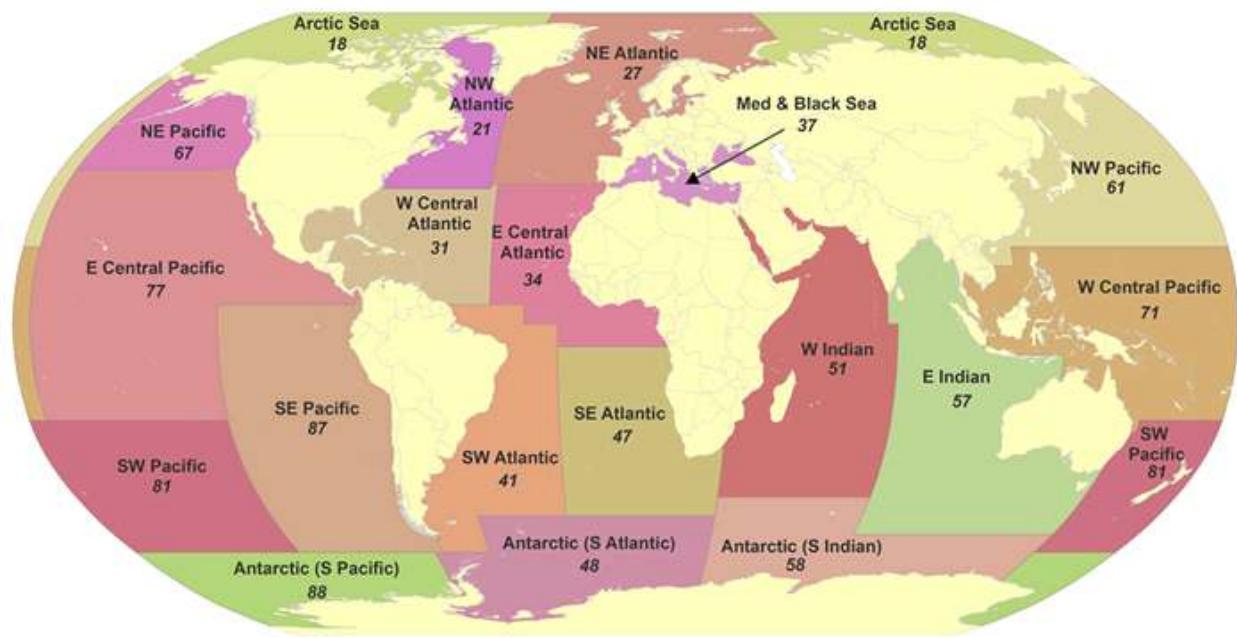

Figure S4. FAO Statistical Area (source: *Sea Around Us* Project: www.searroundus.org).

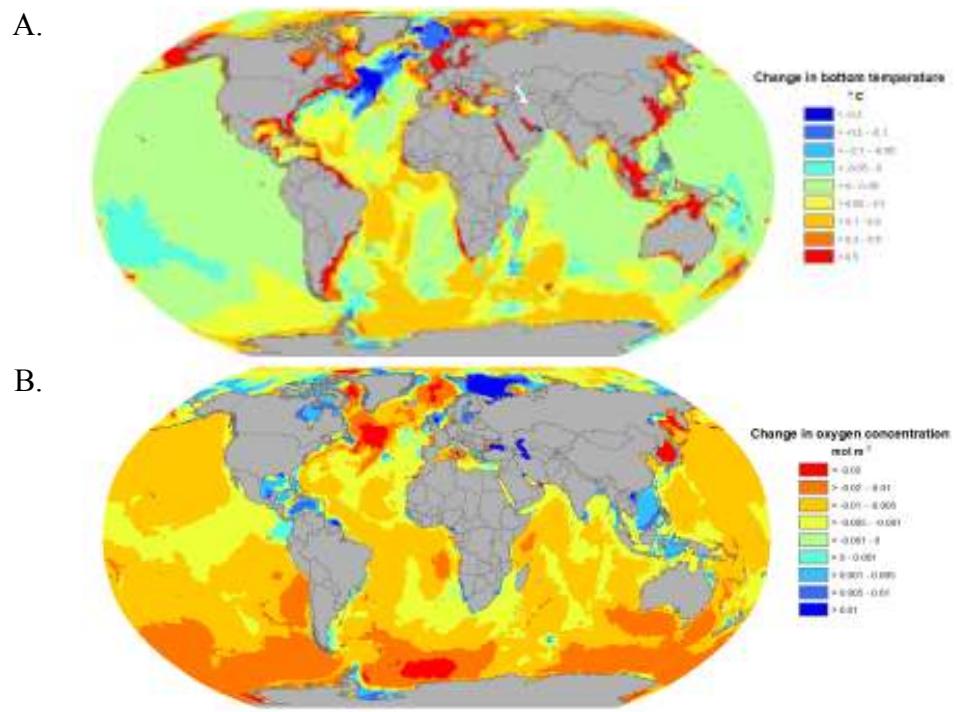

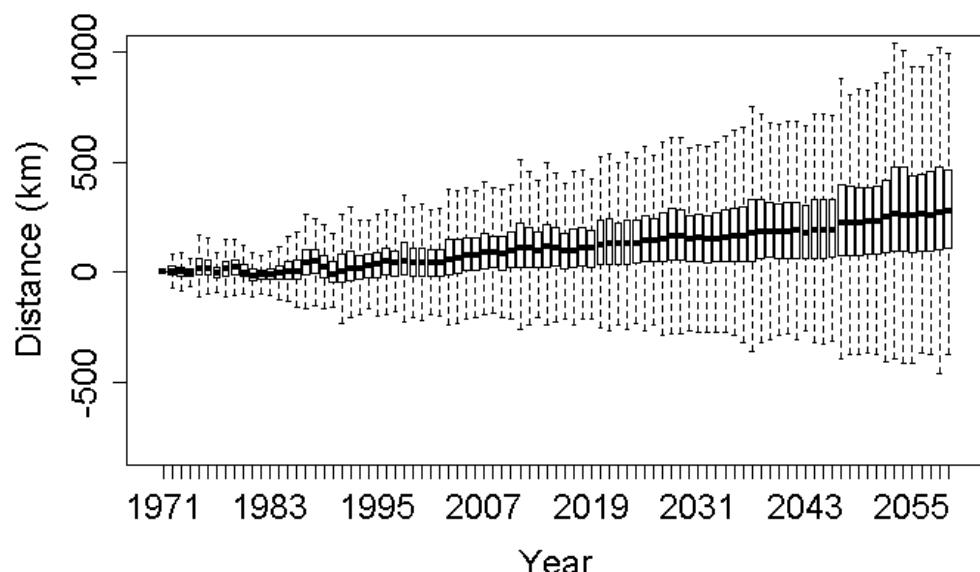

Figure S5. Projected changes in (A) sea bottom temperature and (B) sea bottom oxygen concentration from 1991 – 2000 to 2041 – 2060, averaged between outputs from GFDL ESM 2.1 and IPSL-CM4-LOOP.

a)

b)

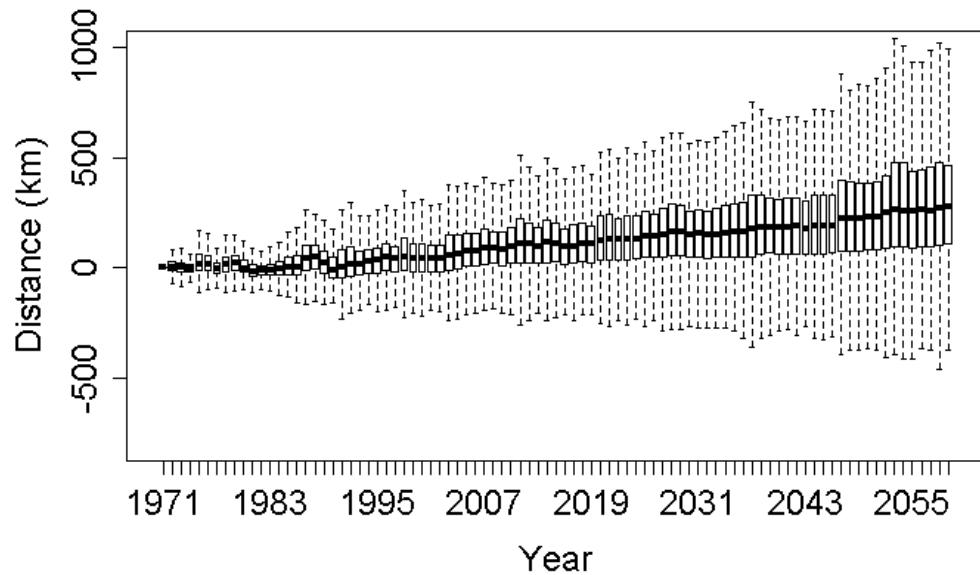

Figure S6. Predicted latitudinal shift of distribution centroids of 610 species of demersal fishes from 1971 to 2060 under the SRES A2 scenario based on outputs from (A) GFDL ESM2.1 and (B) IPSL-CM4-LOOP. The thick dark bar represents the median shift of all the species in a year, the lower and upper boundaries of the box represent the 25% and 75% quartiles, respectively. Positive value indicates poleward shift relative to average latitudinal centroids in 1971 - 2000.

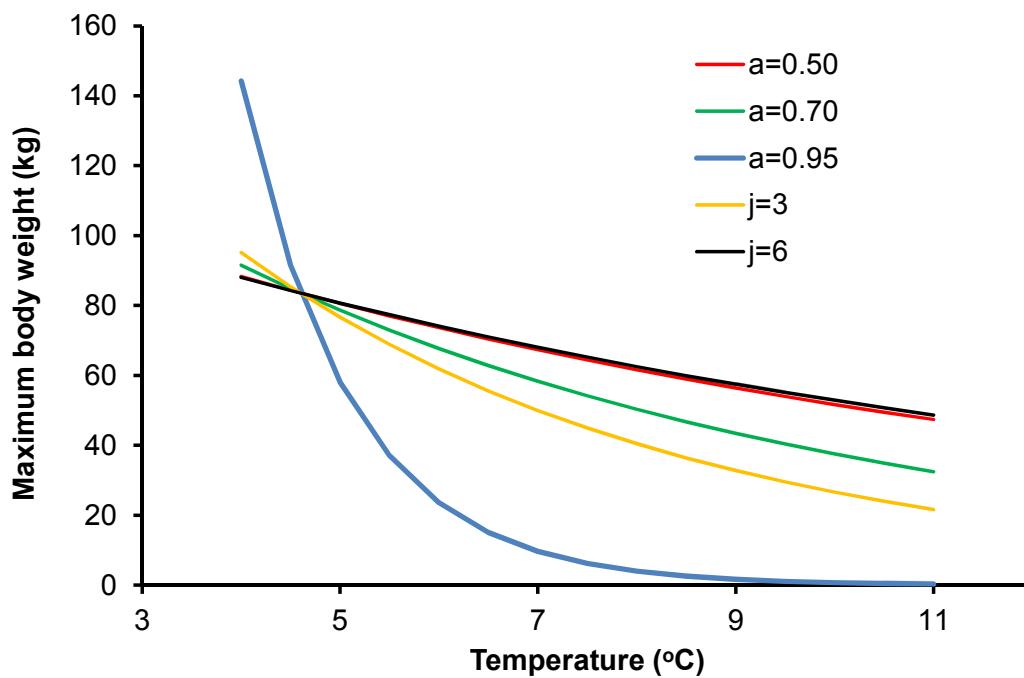

Figure S7. Predicted change in maximum body size for Atlantic cod under different environmental temperature from alternative parameter values for the growth and metabolic scaling models: (1) parameter $a = 0.50$, (2) parameter $a = 0.7$, (3) parameter $a = 0.95$, (4) parameter $j = 3$, (5) parameter $j = 6$.

Table S1. List of fish species included in the analysis, with their von Bertalanfy growth parameters (L_∞ and K) and the corresponding parameters of their length-weight relationships (a, b).
